Abstract: Based on the existing evidence, the histological confirmation of lung metastases (LM) is not always necessary, but it may be clinically relevant, depending on possible clinical scenarios. (I) In presence of known and potentially curatively treatable pulmonary or nonpulmonary primary carcinoma, if the appropriate staging is performed, in patients with suspected solitary LM or with a limited number of unilateral LM, the upfront metastasectomy, without previous histopathological confirmation is usually fully justified. In case of lung nodules in patients with nonpulmonary cancer histological confirmation of suspected LM should be attempted whenever possible, by using all possible tools-bronchoscopy, percutaneous biopsies and video-assisted thoracoscopic surgery (VATS). In presence of multiple LM the histological confirmation may be appropriate if surgery for multiple suspected metastases is not an option. In case of bilateral LM: the assessment of chances for complete resection and the functional loss prediction are priorities, rather than preoperative histological confirmation of LM. LM requiring extended lung resection require preoperative histology is necessary whenever possible. (II) In patients with suspected metastases in presence of known, but non-resectable primary, histological confirmation of suspected LM should be attempted only if clinically relevant. (III) If a suspicion on LM exists without the known primary or after a prolonged remission, the biopsy makes sense whenever possible. (IV) If suspected LM exist after the initial, potentially curative resection of the known primary of any localization, the need for histological confirmation depends on the presence or absence of the primary tumour recurrence. (V) In patients with suspected LM after previous lung metastasectomy, the histological diagnosis is usually not mandatory, because of the radiographic (CT) aspect that is usually highly suggestive of LM. (VI) In presence of suspected LM synchronous with solitary controllable metastases in other organs, although histological confirmation of LM in this situation is not mandatory, it may be appropriate in suitable peripheral lesions of sufficient size.

Introduction

Based on the widespread practice in most of the centers, preoperative histological confirmation before the lung metastasectomy is rarely performed. However, an attempt to check the appropriateness of this practice throughout the literature is not easy. In fact, no studies specifically addressed that issue, so that the above asked question can be answered only indirectly from the existing evidence or

by asking this question in another way, like “what is the true value of lung metastasectomy” or “when is the preoperative histology certainly not necessary”?

There is no answer that could fit for most of the clinical scenarios. There are too many factors that influence the decision whether histological confirmation of suspected lung metastases (LM) is necessary, like the presence or absence of the known primary tumour, tumour stage and ability to control it, tumour histology, limitations of

histological diagnostics, age, fitness for surgery, timing of metastases appearance, or the number and location of metastases. Furthermore, the widespread use of video-assisted thoracoscopic surgery (VATS) procedures has changed the usual delineation line between classical biopsy and therapeutic procedures.

Before discussing possible clinical situations, some common prerequisites for the lung metastasectomy with curative intent deserves to be mentioned: (I) the primary tumour must be under control or controllable; (II) no evidence about distant uncontrollable metastases; (III) the tumor must be resectable, the pulmonary reserve must be adequate; (IV) there are no available therapeutic alternatives with lower morbidity. The term “controllable” primary tumor means that the potential surgical “eradication” of the tumor may be predicted with high probability at the time of diagnosis (1).

In case of CT-PET positive nodes, routine video-mediastinoscopy before the lung metastasectomy is the usual practice in many centers (2), but is not routinely recommended in all below described clinical situations.

Solitary/multiple uni-/bilateral lung lesions in presence of known and potentially curatively treatable pulmonary or nonpulmonary primary carcinoma

Only 15% to 25% of patients with LM are appropriate candidates for surgery (3). For this reason, in this group, more important than the need to provide the preoperative histology is to perform the appropriate staging for extrapulmonary metastatic spread by means of computerized tomography (CT) of the chest and abdomen and, when necessary, by positron-emission tomography (PET) scan and brain imaging with either magnetic resonance imaging (MRI) or CT (4).

If the appropriate staging is performed, in patients with suspected solitary LM or with a limited number of unilateral LM, the upfront metastasectomy, without previous histopathological confirmation is fully justified. This because in the reported series of metastasectomies between 1985 and 2010, 5- and 10-year survival rates were 35% to 45% and 20% to 30%, respectively. Higher survival rates for patients with single lesions have been reported as well (5).

If the suspected solitary metastasis is located in the lung contralateral to the primary tumour-bearing lung, either metastasectomy, or primary tumour resection may be done

first. Beside the clear functional advantage of performing the more limited resection first, such an approach enables the detection of the synchronous primary and performing the appropriate extent of resection. If *ex tempore* analysis can not reliably distinguish between LM and new primary in presence of primary lung cancer with known histology, the decision about the definitive extent of resection of the LM bearing lung lobe should be postponed and performed in the second act, if necessary.

In rare patients in this group, preoperative histology of the suspected LM may be necessary in presence of more centrally located lung primary whose histology could not be established by bronchoscopy or/and mediastinoscopy and whose radiographic morphology suggests the possible small-cell type.

Lung nodules in patients with nonpulmonary cancer

In this group of patients, histological confirmation of suspected LM should be attempted whenever possible, by using all possible tools-bronchoscopy, percutaneous biopsies and VATS. This because retrospective data in populations of patients with cancer show a high frequency of benign lesions (up to 58%) and primary lung cancers (up to 50%) found after biopsies or surgery for pulmonary nodules (PN) (6). In some reports lower rates of malignant nodules were reported, like in 151 patients with extrapulmonary cancers who underwent PN biopsy, with 42% of the nodules were found to be malignant, including newly diagnosed lung cancers (7).

Concerning the prognostic factors, in a study on 228 patients with nonpulmonary malignancy who underwent a biopsy and 64% with LM, (second primary lung tumour in 26.3%, no malignancy in 9.6%), the presence of multiple PNs (>5 mm) and cavitation/necrosis were the only significant factors suggestive of metastatic disease (8). Some other factors, such as primary site, nodule size or concomitant extrapulmonary lesions have been predictive of malignancy in some studies as well (7,8).

The significance of biopsy is additionally supported by some rare reports of change in immunohistochemical profile: for example, the primary breast cancer may be estrogen receptor negative and PR negative, and the pulmonary nodule may be PR positive. This may be important in terms of the more effective treatment for breast cancer recurrence (9,10).

Concerning invasive diagnostics in this group, the specificity of LM is that some of them, despite typical

ovoid-shaped radiographic aspect and intraparenchymal growth, may have a partly endobronchial growth as well. Some studies, by combining forceps biopsies with brush cytology, reported the 84.2% positivity of the endobronchial biopsy with endobronchial lesions and in 60.7% of patients with normal endobronchial finding (11). Some other authors do not suggest fiber-bronchoscopy in patients with a low probability of endobronchial pathology (12). The reports of correlation between atelectasis and endobronchial metastases and a higher rate of histological diagnosis are well known since a long time ago (13,14). Metastases of colorectal carcinoma and carcinoma of the kidney were reported long ago to be associated with frequent endobronchial growth, although for the latter it was not as frequent in some series (15,16).

Transcutaneous fine needle-aspiration biopsy (FNAB) is another diagnostic tool in patients with suspected LM, in whom the diagnosis is unlikely to be obtained by bronchoscopy. The FNAB may be done either US- or CT-guided and provides samples for cytology. If cutting needles are used, histological diagnosis is possible, thus improving overall diagnostic accuracy (17). By using FNAB with histological samples, owing to the accurate diagnosis of benign lesions has reduced the need for diagnostic surgery by up to 50% (18,19).

Multiple LM

The survey conducted by the European Society of Thoracic Surgeons (ESTS) showed that in the current European practice, 85% of respondents do not believe that multiple metastases represent a contraindication for metastasectomy, and none of the respondents regarded the presence of multiple metastases as an absolute contraindication (20).

The easiest scenario exists in patients with more than one suspected LM in the primary tumour-bearing lung lobe, that can be removed with the operative specimen, so that no preoperative histology of LM is necessary.

Some reports included very high numbers of metastasectomies, such as a report on laser surgery allowing minimal loss of parenchyma. In one report, in a group of 328 patients, an average of 10 lesions per patient were removed (21). In one patient with disseminated breast cancer, as many as 124 pulmonary metastases were resected.

However, the evidence suggests a correlation between the number of LM and survival. In 1995, in a study of 38 patients who had been operated on in 12 hospitals, all patients with removal of four or more pulmonary

metastases had tumor progression within 16 months, whereas 50% of patients with less than four metastases were still alive without evidence of disease 5 years after metastasectomy (22).

As the number of LM reflects the degree of tumour dissemination, the histological confirmation may be appropriate if surgery for multiple suspected metastases is not an option, like in patients with numerous large metastases and high tumour grade (23). In this situation definitive nonsurgical treatment of the known primary (although itself resectable) is not indicated and some multidisciplinary teams sometimes require the histological confirmation of LM prior to start with chemotherapy protocols. VATS is usually an appropriate option in this situation.

However, the primary tumour histology and tumour grade are prognostically important. In patients with lung metastasectomies from bone and soft tissue sarcoma, around 15% of patients were reported to have more than 4 lesions, what was prognostically less favourable in comparison with solitary lesions. In addition, a worse survival was observed in a series of 214 patients when the size of LM was >2 cm (24). A disease-free interval of more than 12 months before the development of metastases was also reported a favorable prognostic factor (25).

Bilateral LM

The suspicion of bilateral LM in presence of treatable primary tumour is more challenging. The oncological benefit of bilateral metastasectomy is supported by some studies that did not confirm the worse survival after bilateral compared to unilateral metastasectomy (26,27). In this group of patients, the assessment of chances for complete resection and the functional loss prediction are priorities, rather than preoperative histological confirmation of LM.

The preoperative lung function prediction should follow the existing guidelines by using the calculation of the predicted postoperative forced expiratory volume in 1 second (ppoFEV1). Some additional informations can be obtained by using vibration response imaging (28), quantitative CT (29) and single photon emission CT (SPECT) (30). Also, when a bilateral operation is planned, a diaphragm movement assessment should not be underestimated, as recently demonstrated (31).

The operative approach may be VATS or open, either in form of bilateral thoracotomies (simultaneous/successive) or sternotomy. The suitability of subxiphoid approach for

bilateral LM was also demonstrated (2). An advantage of VATS approach in these patients is the possibility to get the histological confirmation in borderline cases before the definitive decision for bilateral metastasectomy.

LM requiring extended lung resection

Nowadays a major lung resection is not considered an absolute contraindication for metastasectomy, provided that complete resection is possible (32). Extensive and combined resections can be performed with low operative mortality, morbidity and an acceptable long-term survival (33). In these patients preoperative histology is necessary whenever possible. In central tumours bronchoscopy is indicated with all available biopsy devices (biopsy forceps, brush, catheter TBNA). For peripheral tumours invading the chest wall and requiring a subsequent lobectomy with the chest wall resection, transthoracic US- or CT-guided FNAB is necessary.

Suspected metastases in presence of known, but non-resectable primary

In this group of patients, histological confirmation of suspected LM should be attempted only if clinically relevant. This because in a high proportion of these patients some forms of specific oncological treatment has already been started before the occurrence of suspected LM.

If the non-resectable primary is detected by imaging (CT, PET/CT, MRI), but for any reason without histological confirmation, a biopsy of the suspected LM is indicated by bronchoscopy, imaging-guided FNAB or by VATS, depending on the lesion(s) localization. In presence of synchronous pleural effusion, a thoracoscopic biopsy may reveal pleural carcinosis, even if not suspect on imaging, thus providing the histological confirmation of malignancy (34).

In patients who are for any reason allocated for palliative treatment for the primary tumour, histological diagnosis of LM is not necessary.

Solitary/multiple uni-/bilateral lung lesions, suspect on LM, without the known primary or after a prolonged remission

Unlike patients with known primary and multiple lung lesions, in whom biopsy is unlikely to alter the presumed diagnosis of metastases, in the absence of the known

primary, the biopsy makes sense whenever possible (35). This because the radiographic aspect of slowly growing or newly developed nodules may exist in patients with benign diseases such as rheumatoid or Wegener's or other granulomatosis, or with infections (especially in immunocompromised patients) and can be diagnosed by biopsy (36,37).

This group of patients includes those with small, sub-centimeter nodules, including ground-glass opacities (GGO) and greater nodes with diameter >5 cm or more. Despite a limited value of PET/CT in presence of nodules <8 mm, especially in pure ground-glass nodes, some recent studies have rebuilt its diagnostic value in patients with solitary pulmonary nodules. A latest meta-analysis suggested that PET/CT is still a useful method for qualitative detecting of malignant pulmonary nodules (38).

Although some cases of metastatic lung tumor showing GGOs from adenocarcinoma of the gastrointestinal tract and malignant melanoma have been reported, GGO due to a metastatic tumor is uncommon (39,40). However, this possibility should be also kept in mind. Currently, the diagnostic workup (follow up or invasive diagnostics) in presence of GGO-s is based mostly on the size of the lesion. According to Fleischner Society guidelines, the cutoff value of diameter sub-solid nodule is set as 5 mm and if solitary pure GGNs ≤ 5 mm, no CT follow-up is necessary, whilst multiple pure GGNs ≤ 5 mm should be followed-up by CT at 2 and 4 years. Initial follow-up CT at 3 months is needed and recommended to confirm persistence. The biopsy or surgical resection is recommended for persistent, dominant nodules with part-solid or solid component, especially for lesions with >5 mm solid component (41). In 2006. The NELSON trial reported about the value of volumetric measurements to identify nodules predictive of lung cancer. Nodules with a volume <100 mm³ were not found as predictive of lung cancer, whilst for nodes with a volume 100–300 mm³ the volume doubling time assessment was suggested (42). The combination of all available diagnostic tools, such as EBUS, electromagnetic navigation bronchoscopy, virtual bronchoscopic navigation, VATS and open surgical biopsies is recommended to improve the diagnostic yield for pulmonary nodules (43).

In patients with a prolonged remission after initial oncological treatment, confirmation of recurrence is frequently required in order to plan further treatment. In this situation, the diagnostic work-up is performed as previously described for clinical scenarios 1 and 3.

In the group of patients with unknown primary,

Figure 1 A big metastasis after previous lobectomy for primary left-sided lung cancer; because of the poor lung quality, operation or than rest-pneumonectomy is not possible.

VATS biopsy has some clear advantages *vs.* other biopsy techniques, mostly relating to some histological issues. Indeed, there are two possible scenarios in practice: (I) LM (either adenocarcinoma or other than adenocarcinoma) with microscopic features suggesting probable sites of origin; (II) LM whose morphology offers limited informations about the site of origin. For example, in a metastatic lesion, the presence of solid nests and trabeculae composed of tumor cells with limited nuclear pleomorphism, punctate areas of necrosis suggestive of comedocarcinoma, or trabeculae composed of small hyperchromatic tumor cells strongly suggests the possibility of a breast origin, particularly in a female patient (44). Or, the presence of prominent glandular formation in a metastatic tumor in bone or brain suggests the possibility of a pulmonary origin for the lesion (45). Among tumours other than adenocarcinoma listed under the scenario 1, metastatic neuroendocrine, sarcomatoid carcinomas or metastatic germ cell tumours may be encountered. The diagnosis of the latter group suggests the need to exclude primary lesions in the gonads, mediastinum, and central nervous system (46,47). The aforementioned considerations relate to surgically removed specimens and even then, it is not easy to establish the diagnosis. As the lesion removed by VATS offers a significantly greater volume of tissue *vs.* biopsy specimens obtained by other methods, it is clear that after VATS, the possible primary tumour is more reliably suggested, and further diagnostics

more accurately directed.

Suspected LM after the initial, potentially curative resection of the known primary of any localization

In patients with suspected LM in the absence of local recurrence after the operation for extrapulmonary primary, potentially curative treatment can be planned. In this case, preoperative histology is not mandatory. Importantly, independently of presence or absence of symptoms, the local status at the site of the previously resected tumour must be checked, not only by imaging, but by endoscopy as well, whenever possible (laryngoscopy, bronchoscopy, esophagogastroscope, colonoscopy, cystoscopy etc. depending on localization).

In case of local recurrence, eventual biopsy (surgical or nonsurgical) may be required for further oncological treatment.

Some recent studies suggest the appropriateness of histological confirmation of solitary lung nodules in patients with previous malignancies in order to optimize treatment, like a study on 140 patients with prior known malignancies and lung nodules removed by VATS. In this series, only 50% of resected nodules were metastases, whilst a newly diagnosed lung primary was detected in 25% of the resected specimens. Upper lobe localization and $SUV_{max} > 2.5$ were predictors of malignancy. With the exception of the smoking status, no other factors could delineate between primary lung cancer and metastases (48). These data may be of help in decision making process in patients with such a clinical scenario.

In patients with suspected ipsilateral LM after initial lobectomy or bilobectomy for primary lung cancer, histological diagnosis of the LM is not always feasible and, more importantly, not really necessary. If PET/CT indicates the presence of resectable lesion, usually located deeper in the lungs, either sublobar resection, or even completion pneumonectomy may be indicated (*Figure 1*).

After the initial sublobar resection, a rest-lobectomy is sometimes possible, but not infrequently with some of the broncho- or vasculoplastic procedures. In patients with a limited lung function, nonsurgical alternatives, such as stereotactic radiation therapy, are also available.

If a suspicion on LM exists after previous contralateral lobectomy, the position and motility of the both diaphragms should be checked (*Figure 2*).

After pneumonectomy, metastasectomy is rare, but

Figure 2 Solitary lesion in the right lung after contralateral lobectomy with elevated left hemidiaphragm: motility of the right diaphragm should be checked.

Figure 3 Solitary metastasis after the right pneumonectomy (arrow indicates the lung lesion).

has also been reported (*Figure 3*). Of course, in this case functional assessment is the priority, rather than histological confirmation of suspected LM. In the four largest series ever published, only two out of a total of 65 patients underwent a lobectomy while the remaining 63 had wedges or segmentectomies (49,50).

Suspected LM after previous lung metastasectomy

In patients in this group who are candidates for redo surgery, the histological diagnosis is usually not mandatory, because of the radiographic (CT) aspect that is usually highly suggestive of LM. The praxis of repeated metastasectomies seems to be underreported. There are no widely accepted recommendations and open surgery is

performed in a majority of patients.

Rare studies on reoperations for LM reported an interesting finding: in a group of 113 patients with 2–6 lung metastasectomies, tumors initially showed a less aggressive biological pattern, followed by more malignant course, non responsive to conservative treatment, without the increase in perioperative mortality or morbidity (51). Furthermore, tumour size, number of resections and probability of recurrence directly correlated with the number of operation, whereas an inverse correlation existed between these factors and disease free interval, that became shortened. It seems that redo metastasectomy may be appropriate for the initial procedures, whilst afterwards, because of the decrease of disease-free and overall survival, surgical therapy loses its efficacy.

In patients with a limited lung function, nonsurgical

Figure 4 Small solitary metastasis in the left lung after previous ipsilateral metastasectomy in patient with severely limited lung function.

alternatives, such as stereotactic radiation therapy should be considered as well (*Figure 4*).

Suspected LM synchronous with solitary controllable metastases in other organs

Nowadays, the presence of simultaneous lung and liver metastases should not be considered an absolute exclusion criterion for metastasectomy. Although histological confirmation of LM in this situation is not mandatory, it can be done in suitable peripheral lesions of sufficient size. Synchronous liver metastases can be biopsied as well under US or CT guidance. In selected patients, combined one stage multi lung-liver resections demonstrated a long term survival (52). However, based on poor reported outcome, in the presence of high levels of CEA plus CA19-9 at first metastasectomy, surgery should be carefully reconsidered.

Isolated LM synchronous with solitary brain metastasis does not represent a contraindication for surgery, provided there is no other distant spread.

Conclusions

Based on the existing evidence, the histological confirmation of lung LM is not always necessary, but it may be clinically relevant in selected patients. Although there are no recommendations that could refer to most of the patients, the presented evidence could help in avoiding unnecessary biopsies, in the same time not omitting them when clinically relevant. By allocating the patients into the described clinical scenarios prior to decision about diagnostics, taking account of available technical resources and personal skills, an appropriate decision may be facilitated.
